Abstract

Gizzard shad (*Dorosoma cepedianum*) are a common freshwater fish found throughout the central and eastern portions of North America. Within these areas, gizzard shad play a number of critical roles in the freshwater community. Because of this, it is important that we understand how gizzard shad populations respond to environmental changes and what these changes may mean for aquatic communities in general and fish assemblages in particular. Here we introduce an integral projection model (IPM) for gizzard shad based on empirical data and include in the model density-dependent survival in age-0 fish. Integral projection models are a generalization of stage-based, matrix population models that have been used to describe a wide range of organisms. IPMs are a natural choice for gizzard shad since many aspects of their life cycle have been studied. In this paper, we compared model outcomes to empirical patterns reported for this fish species at a key location along the Illinois River (La Grange Reach). Results of our work suggest that this model could serve as an important tool for predicting gizzard shad population responses to changing environmental conditions, including those mediated through species invasions.

Keywords: population dynamics, fisheries, Mississippi River basin, population ecology, invasive species impact

1. Introduction

Gizzard shad (*Dorosoma cepedianum*) is a laterally compressed, deep-bodied fish species that occupies numerous aquatic systems throughout central, southern and eastern regions of the United States (Pierce et al., 1981; Vanni et al., 2005). In more eutrophic habitats,

such as reservoirs, gizzard shad can reach high abundances leading to its dominance within fish assemblages. Because of this, gizzard shad have the potential to influence freshwater systems in a number of ways. First, young shad often serve as a critical food source for many fish species, including those of commercial and recreational importance (such as walleye and largemouth bass)(Jester et al., 1972). Thus, gizzard shad can serve as an important trophic link within aquatic food webs. Second, because detritus can serve as a primary food source throughout much of gizzard shad development (i.e. from the age-0 stage onward), these fish can transport nutrients from benthic regions into pelagic habitats (Mather et al., 1995; Schaus and Vanni, 2000; Vanni et al., 2005). This process can result in an increase in the nutrients available to organisms within the water column leading to increases in phytoplankton biomass, algal blooms, and, due to these conditions, shifts in freshwater community structure (Aday et al., 2003; Schaus and Vanni, 2000). Finally, the fact that detritus can comprise a substantial portion of gizzard shad diet also makes this species an important connection between terrestrial inputs and aquatic processes (Schaus and Vanni, 2000). Given its potentially important role in aquatic ecosystems, interest has intensified in understanding how gizzard shad populations respond to environmental changes (both natural and anthropogenic) and what these changes may mean for freshwater communities in general and fish assemblages in particular.

Interactions within and between species throughout interconnected environments can have important consequences for fish populations across space and time (Thorp et al., 2006). For gizzard shad, previous work has suggested that fish densities can play an important role in both the growth and survival patterns observed in populations of these fish. For example, (Buynak et al., 1992) reported an inverse relationship between densities and the lengths of age-0 gizzard shad. Similarly (Welker et al., 1994) found that high densities of age-0 shad were negatively associated with both fish length and survival under both field and semi-natural conditions. Finally, (Michaletz, 2010) reported that the densities of age-0 gizzard shad were negatively correlated with survival in two Missouri lakes. These patterns were attributed to intraspecific competition among young shad for prey (zooplankton) resources. Although intraspecific competition may be influencing life-history traits in subsequent stages of gizzard shad development, little work has actually been conducted to address this (Di-

Cenzo et al., 1996). There is also evidence that the densities of other co-occurring fish species (such as invasive carps) may also negatively influence aspects of gizzard shad biology, such as body condition (Irons et al., 2007; Love et al., 2018).

Although substantial empirical work on gizzard shad biology has accumulated over the decades, few if any studies have attempted to use these data to model population dynamics in this species. Work by Catalano and Allen (2010, 2011) used empirically-based simulations of gizzard shad to assess population-level responses in this species. As part of this process, the authors investigated population-structure using fish lengths but did not consider the impacts of gizzard shad densities on population patterns. Here, we introduce an integral projection model for gizzard shad based on empirical data with density-dependent survival in age-0 fish. We then compare model outcomes to the dynamics reported for this fish species in a well-studied pool of the Illinois River (La Grange Reach). Results from this work suggest that our model could be an important tool for predicting gizzard shad population responses to changing environmental conditions, including those mediated through species invasions (i.e., silver and bighead carp).

2. Model development

2.1. Gizzard shad life history

Mature gizzard shad tend to mate between May and June, although this can vary based on water temperatures.. Males and females aggregate and then broadcast gametes into the surrounding water; fertilized eggs then settle and adhere to the bottom substrates. After a period of days, eggs hatch and fish develop from the larval stage to juveniles and eventually to adults. In many habitats, individuals can reach sexual maturity within a year. As gizzard shad mature, their diet preferences typically shift from phytoplankton and zooplankton early in development to detritus and zooplankton as adults. Given the large number of eggs produced by shad females ($> 300,000/\text{year}$), there is evidence that intraspecific competition can be intense during early developmental stages in this species leading to density-dependent survival. The strength of competition may then subside as fish transition to feeding on different food items during latter stages of development.

Table 1: A summary of parameters, their biological meaning, and source for mean values.

Parameter	Meaning (units)	Mean	Source
Logistic survival probability function, $s(z)$			
s_{\min}	minimum survival	0.002	(Bodola, 1955)
s_{\max}	maximum survival	$1 - 8.871K^{0.73}L_{\infty}^{-0.33}$	THEN 2015
α_s	inflection point	104.34	Estimated from LTRM dataset
β_s	slope	-637.93	Estimated from LTRM dataset
Growth function, $G(z, z')$			
L_{∞}	maximum length (in mm)	394.30	(Catalano and Allen, 2010)
K_g	growth rate	0.26	(Michaletz, 2017)
σ_g	growth standard deviation	25	(Michaletz, 2017)
Normal distribution of length of age-1, $C_1(z')$			
μ_r	mean length of recruitment (in mm)	105	(Michaletz, 2017)
σ_r	standard deviation of length	25	(Michaletz, 2017)
Eggs produced, $\text{egg}(z)$			
egg_{\max}	maximum number of eggs produced	742,094	Estimated from (Jons and Miranda, 1997)
α_e	inflection point	314.44	Estimated from (Jons and Miranda, 1997)
β_e	slope	-7.12	Estimated from (Jons and Miranda, 1997)
Survival of age-0, $s_0(d(t))$			
a_0	intercept	0.27	Estimated from (Michaletz, 2010)
b_0	decay rate	0.003	Estimated from (Michaletz, 2010)
Spawning			
ν	probability that egg becomes viable	0.002	(Bodola, 1955)
p_b	probability that female spawns	0.90	

2.2. Equations

We used an integral projection model (IPM) to describe the life history of gizzard shad in the Upper Mississippi River (UMR) system. IPMs were first introduced by Easterling (Easterling et al., 2000), as a generalization of stage-based, matrix population models. Since that time, IPMs have been used to describe a wide range of organisms (Ellner et al., 2016; Merow et al., 2014; Rees et al., 2014), but have only recently been used to model fish populations (Erickson et al., 2017; Liao et al., 2019; White et al., 2016; Pollesch et al., 2022). Fish are an ideal group to investigate using this approach as many species have been well studied and are therefore associated with robust information about life-history traits (i.e. growth and reproduction). Gizzard shad are one such species and have been the subject of numerous laboratory and field studies over the decades making it a logical choice for IPMs. In our model specifically, we incorporate data from studies on 1) egg production in different size classes of fish, 2) density-dependent survival of age-0 shad, and 3) length distributions of gizzard shad in the UMRS that span nearly thirty years.

We assumed that variations among individual gizzard shad can be summarized by its length z (in mm) ranging from the minimum possible length L to the maximum value U . The state of the population at time t (in years) is described by the length distribution $n(z, t)$. Specifically, for each time t , $n(z, t)$ is a smooth function of z such that the number of individuals of length z in the interval $[a, b]$ at time t is $\int_a^b n(z, t) dz$.

Between times t and $t + 1$, individual gizzard shad may grow, die, and produce offspring that vary in length depending on the individual's current length (Figure 2). At time $t + 1$ the population will have a length distribution defined by $n(z, t + 1)$. For our model, we partition the life cycle of gizzard shad into two compartments: 1) survival and growth, and 2) reproduction. For an individual of length z at time t , $P(z', z)\Delta z$ is the probability that the individual is alive at time $t + 1$, and its size is in the interval $[z', z' + \Delta z]$ (as with $n(z, t)$ this is an approximation that is valid for small Δz , and the exact probability is given by an integral like the one above). Similarly, $F(z', z)\Delta z$ is the number of new offspring in the interval $[z', z' + \Delta z]$ present at time $t + 1$, per length- z individual at time t .

Figure 2: Life cycle diagram and census points for pre-reproduction census of gizzard shad.

2.2.1. Growth and survival

We define $P(z'z) = s(z, T)G(z', z)$ where $s(z)$ is the adult annual survival probability and $G(z', z)$ describes the annual length transitions. We assumed that the survival function is a logistic function,

$$s(z, T) = s_{\min} + \frac{s_{\max} - s_{\min}}{1 + e^{\beta_s(\ln(z) - \ln(\alpha_s))}}. \quad (1)$$

with four parameters: the minimum survival rate s_{\min} ; a maximum survival rate, s_{\max} ; an intercept parameter, α_s ; and a slope parameter, β_s (Bolker, 2008).

We assumed that the growth function is a two-variable normal distribution centered around a modified von Bertalanffy function of the length at time t . The von Bertalanffy equation, commonly used to describe the length of a fish over time, is given by $z(t) = L_{\infty} (1 - e^{-K(t-t_0)})$ where L_{∞} is maximum asymptotic length, K is the growth rate, and t_0 is the initial time. The expected fish length the following year is:

$$\begin{aligned} z' = z(t+1) &= L_{\infty} (1 - e^{-K(t+1-t_0)}) = L_{\infty} - L_{\infty} e^{-K(t-t_0)} e^{-K} \\ &= L_{\infty} - (z(t) - L_{\infty}) e^{-K} = L_{\infty} (1 - e^{-K}) + z(t) e^{-K}. \end{aligned}$$

Consequently, we assumed that $G(z', z) = \text{Prob}(z' | z, L_{\infty}, K_g) = \text{NormalPDF}(\mu_g, \sigma_g)$ where K_g is the individual growth rate, $\mu_g = L_{\infty} (1 - e^{-K_g}) + z(t) e^{-K_g}$, and σ_g is the standard deviation.

2.3. Fecundity

We define the fecundity kernel,

$$F(z', z) = p_b \text{egg}(z) \nu s_0(n(z, t)) C_1(z') \quad (2)$$

where p_b is the probability of reproducing, $\text{egg}(z)$ is the mean number of eggs produced, ν is the probability that an egg is viable, $s_0(n(z, t))$ is the density-dependent probability of surviving to age-1, and $C_1(z')$ is the length distribution of new recruits at age-1 (when they are first censused).

We assumed that the mean number of eggs produced by females of a certain length is a three-parameter logistic function,

$$\text{egg}(z) = \frac{\text{egg}_{\max}}{1 + e^{\beta_e(\ln(z) - \ln(\alpha_e))}}. \quad (3)$$

The probability of gizzard shad survival during their first year can depend on many factors (Michaletz, 2010) including predation, temperature, the mean total length of fish, and the density of age-0 fish. In this study, we focus only on the density factor and define the probability of survival of age-0 fish as the exponential function

$$s_0(d(t)) = a_0 e^{-b_0 d(t)} \quad (4)$$

where a_0 is the intercept, b_0 the decay rate, and $d(t)$ is the density at time t of age-0 gizzard shad per 1000 m³,

$$d(t) = 10^{-3} \int_L^U p_b \text{egg}(z) \nu n(z, t) dz.$$

Finally, we computed the total number of eggs that result in age-1 fish and multiplied this number with a normal distribution of length, $C_1(z') = \text{NormalPDF}(\mu_r, \sigma_r)$ where μ_r is the mean length of age-1 gizzard shad and σ_r is the standard deviation.

2.4. Dynamical model

The population at time $t + 1$ is the sum of the contributions from each individual alive at time t ,

$$n(z', t + 1) = \int_L^U K(z', z) n(z, t) dz, \quad (5)$$

where $K(z', z) = s(z)G(z', z) + F(z', z)$ and $[L, U]$ is the range of all possible lengths.

3. Methods

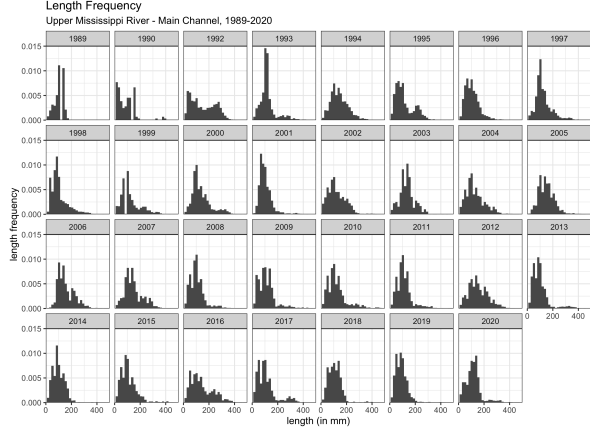

3.1. LTRM data and model parameterization

The integrity and health of the UMRS is assessed through Long Term Resource Monitoring (LTRM) which is overseen by a number of agencies including the U.S. Army Corp of Engineers, the United States Geological Survey and the United States Fish and Wildlife Service. The goal of the LTRM is track changes in the condition and/or stability of the UMRS ecosystem and participate in restoration activities throughout the region. In order to achieve this goal, numerous features of the UMRS, such as aquatic vegetation, bathymetry, fish, land use/land cover, and water quality are continually surveyed from Navigation Pool 1 (at Minneapolis, Minnesota) south to the confluence of the Mississippi and Ohio Rivers at Cairo, Illinois. The LTRM fish surveys are conducted at five locations along the main channel of the Upper Mississippi River (Pools 4, 8, 13, 26, and the Open River Reach) and at one location along the Illinois River (La Grange Reach) (Figure 3a). Fish are captured using a multiple gear approach (including netting and electrofishing) in order to monitor the responses and health of fish communities along these two very important waterways over time (Gutreuter et al., 1995). Specific capture methodologies, protocols and modifications to the LTRM can be found in Gutreuter et al. (1995), and Ickes and Burkhardt (2002). In terms of gizzard shad, fish traits (such as total length) have been recorded since 1989 with approximately 3000 collections occurring per year along the Mississippi River (Figure 3b). For the La Grange Reach of the Illinois River, gizzard shad have been sampled and measured since 1990 with approximately 500 collections occurring per year.

To parameterize our model, we used gizzard shad data collected from the 5 sites along the Mississippi River. We then validated our model using empirical information collected from the La Grange Reach of the Illinois River. We employed this approach as the La Grange Reach is upstream of the Mississippi River making it a more distinct location compared to the other sites.

(a)

(b)

Figure 3: (a) Site source of image. (b) Length frequency of sampled gizzard shad in the main channel of the Upper Mississippi River system.

3.2. Parameterization

3.2.1. Fecundity and recruitment

Female gizzard shad begin reproducing at approximately 140 mm in length and egg numbers tend to increase with fish size (Jons and Miranda, 1997). The logistic parameters for the mean number of eggs produced by females of a certain length were obtained by fitting the three-parameter logistic function (Equation 3) to the data for batch fecundity versus length (Jons and Miranda, 1997) (Figure 4a). Fish survival to age-1 was assumed to be dependent on the density of age-0 gizzard shad (Figure 4b). Parameters for the exponentially decaying age-0 survival function (Equation 4) were determined by fitting equation 4 to the survival means for 2003-2007 cohorts of gizzard shad in five Missouri reservoirs (Michaletz, 2010). To complete the recruitment process we assign a length to the recruited individuals by simulating a Gaussian random variable with mean μ_c and standard deviation σ_c . These parameters for the size distribution of age-1 fish were gleaned from a study of gizzard shad located in large impoundments (Michaletz, 2017) and the historic 1990-2020 LTRM dataset from the main channel of the UMRS (outlined above).

Figure 4: (a) Mean number of eggs produced by female gizzard shad $\text{egg}(z)$. Data from (Jons and Miranda, 1997). (b) Age-0 density-dependent survival function $s_0(d)$. Data from (Michaletz, 2010).

3.2.2. Growth and survival of adults

The parameters for the growth function were chosen as the mean values published on a study of gizzard shad located in large impoundments (Michaletz, 2017). The association between adult lengths and survival have not been well-resolved in gizzard shad leading us to make a number of assumptions. First, we assume that the probability of adult survival is related to the length by a four-parameter logistic function (Equation 1). An investigation of gizzard shad in Lake Erie (Bodola (1955)) provided the minimum and maximum survival rate of adults. Based on the observed length distributions of gizzard shad sampled from the main channel of the Mississippi River (Figure 3b), we assumed that solutions of our model will exhibit periodic behavior every 8-9 years. We used a least squares method to estimate the α_s and β_s parameters that minimized the total square-distance between the (observed) pre-carp LTRM length distribution in the main channel of the UMRS and (predicted) model equilibrium, $n(z, t)$ during a 8-year period 100 years after initialization. The slope parameter β_s was found to be large in magnitude resulting in a primarily two-valued survival probability. Gizzard shad less than α_s mm in length have a very low survival rate (s_{\min}) while lengths larger than α_s mm have the maximum survival rate s_{\max} . This survival pattern has been reported for a number of fish species and can arise due to a number of biotic (i.e. predation) and/or abiotic (i.e. temperature) factors (Pepin et al., 1992; Nowlin et al., 2006).

4. Analysis and results

We numerically solved the integral model using the Midpoint Rule with large approximating matrices (Burden and Faires, 2005). The Midpoint Rule has been commonly used for integral projection models because of its simplicity and effectiveness (Ellner and Rees, 2006; Ramula et al., 2009; Merow et al., 2014). During the course of model development, we explored different step sizes for the Midpoint Rule and found that about 50 points provided numerically stable results. We integrated over lengths from 0 mm to 500 mm. The upper limit was chosen based upon numerical stability and consistency of the system (e.g., avoiding eviction or the loss of individuals due to numerical errors (Williams et al., 2012)).

4.1. Initial conditions

We assumed that the initial density of gizzard shad was $d_0 = 964.7$, the annual average density of gizzard shad observed in La Grange Reach from 1993-2019. The probability of an individual being length z at time $t = 0$ was assumed to be normally distributed with mean $0.5L_\infty$ and standard deviation $\sigma_0 = 30$. As a result, we initialized our model with length distribution

$$n(z, 0) = d_0 \text{Norm}(0.5L_\infty, \sigma_0) = 964.7 \text{Norm}(166, 30). \quad (6)$$

The model was coded in R (R Core Team, 2017) and the scripts are published on JP github page <https://github.com/jppeirce>.

4.1.1. Survival of age-0 cohort

The density of age-0 gizzard shad strongly influences the density of these fish at subsequent developmental stages. When adult densities are large, there may be more fish of longer lengths that can produce greater numbers of eggs. More eggs results in increasing densities of age-0 shad and a subsequent reduction in their survival to age-1 (due to competition). More eggs leads to a higher density of age-0 fish and reflectively a reduction in the survival to age-1. If this reduced survival continues for a few years, the overall density of fish within the epopulation may decline and there may not be as many larger fish reproducing. Fewer fish spawning, could result in a smaller age-0 class which, in turn, could enhance survival in this cohort (through reduced competition). We would then expect the overall density of

Figure 5

Figure 6: Survival probability of age-0 gizzard shad.

Figure 7: (a) The total number of gizzard shad in La Grange Reach predicted by IPM for first 100 years. (b) Simulated length distributions during an 8 year interval of time (approximately 1 period of the the total density function)

fish to increase over the following years, until large numbers of eggs are again produced by larger, adult fish. This oscillatory pattern is reflected in our model by the time-dependent survival probability of age-0 recruits(Figure 5).

4.1.2. Periodic orbit and validation with external dataset

The total number of gizzard shad in our simulation reached a stable periodic orbit (Figure 7a) within 50 years. The length distributions during the periodic orbit (Figure 7b) have similarities to fish lengths observed from the La Grange Reach (Figure 8a). Furthermore, average simulated length distributions reflects the length frequencies reported from the La

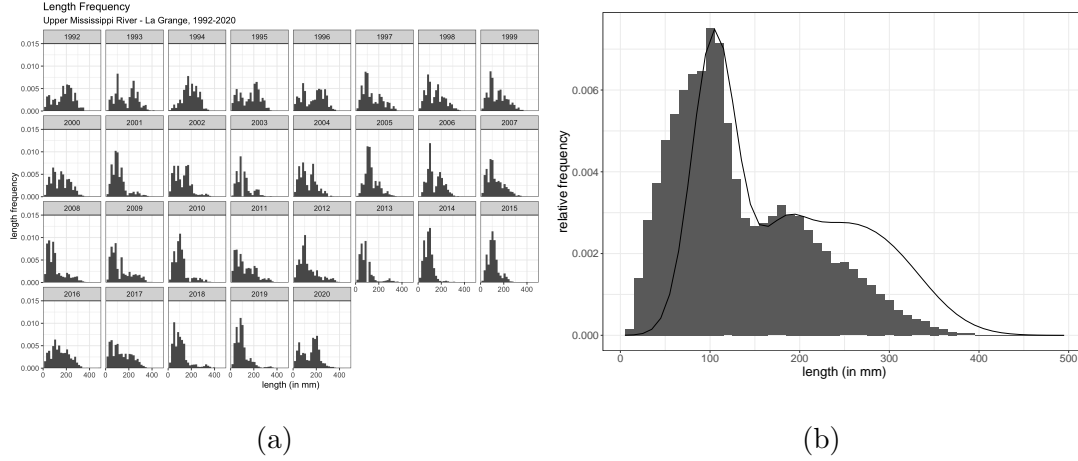

Figure 8: (a) Length frequencies of sampled gizzard shad in La Grange for each year, 1992-2020. (b) Length frequencies of sampled gizzard shad in La Grange from 1992-2020 compared with average (over 1 period) simulated length frequency.

Grange Reach. (Figure 8b).

After simulating an additional 50 years, we fit a periodic function to the annual density of gizzard shad and determined a period of approximately 8.5 years. Figure 7b illustrates the periodic length dynamics within the gizzard shad population during a 8-year window of the periodic orbit. The ebb and flow of the frequency of the age-1 cohort are associated with the density-dependent survival function for age-0 fish as explained in Section 4.1.1. In addition, Figure 7b captures the cohort length dynamics of the gizzard shad. Specifically, the peak length frequency of age-1 fish in Year 1 near $z = 105$ mm is seen as a peak in Year 3 near 185 mm, a peak near 305 mm in Year 3, before becoming nearly unidentifiable in the graphs for Years 7 and 9. This is consistent with the lifespan reported for gizzard that can range, on average, between 4 and 6 years (CITATION). The change in the location of these relative maximum influences the number of eggs being produced and consequently the density of age-0 fish the next year. An increase in the frequency of larger adults leads to a subsequent reduction in the resulting age-1 cohort due to our density-dependent survival function in age-0 fish.

5. Discussion

Gizzard shad are common in freshwater systems of North America where they are important components of the aquatic communities. Given this, it is important to understand how populations of this species vary with changing environmental circumstances, such as the occurrence of invasive species. Herein we use both LTRM data and parameters gleaned from other empirical studies to develop an integral projection model for gizzard shad and test model outputs against patterns reported from a well-studied population of this species from the La Grange Reach of the Illinois River.

After fitting two adult survival parameters using LTRM data from the main channel of the Mississippi River, we compared a simulated length distribution with LTRM data collected from the La Grange Reach of the Illinois River from 1992 to 2020. The resulting simulated length distributions (Figure 7b) reflected a number of the empirical patterns observed in gizzard shad captured from the La Grange Reach over the same timeframe (Figure 8a). Specifically, the two peaks in Year 1 of our simulations are similar to the length patterns in gizzard shad collected from the La Grange Reach in 1997. In the following year, the higher frequency of age-1 fish in our simulations was also seen in the LTRM data (Year 2).

We notice that the peak frequencies are near the same length with the model predicting slightly more adults lengths and fewer juvenile lengths than the observations. This may be explained by gear bias. The methods used to capture fish make it more likely to record longer lengths ($> 200\text{mm}$). Studies [CITATION] suggest that due to the environmental stochasticity and other effects, smaller recruitment fish densities can fluctuate annually and be difficult to measure accurately.

While our model uses age-0 density to effect age-0 survival, we assumed constant viability which may be sensitive to the external factors mentioned above. In addition, the location of the maximum length and the variation in the of length of new recruits recorded in the LTRM data, suggests that there may be smaller age-0 fish in La Grange Reach than in study location (Michaletz, 2017) used to parameterize the model.

While not all observed length distributions are reflected in the simulations, the similarity in the average length distributions (Figure 8b) suggest that our IPM could serve as a tool for predicting length distributions for gizzard shad across different study areas. (LAST

SENTENCE NEEDS A LOT MORE CLARITY)

Gaining an understanding of how length distributions of gizzard shad emerge under density-dependent survival in the age-0 class will serve as a foundation for investigating density effects at subsequent stages in the life cycle. In addition, this single-species model could also be expanded to incorporate interspecific interactions between gizzard shad and species such as invasive carp, which appear to negatively impact gizzard shad life-histories through competition for food resources.

6. Acknowledgments

These data are a product of the U.S. Army Corps of Engineer's Upper Mississippi River Restoration Program (UMRR) Long Term Resource Monitoring (LTRM) element implemented by the U.S. Geological Survey in collaboration with the five Upper Mississippi River System (UMRS) states of Illinois, Iowa, Minnesota, Missouri, and Wisconsin. The U.S. Army Corps of Engineers (Corps) provides guidance and has overall program responsibility.
